Ground-level ozone is a secondary pollutant produced photochemically from the reactions of nitrogen oxides with peroxy radicals produced during volatile organic compound (VOC) degradation. Chemical transport models use simplified representations of this complex gas-phase chemistry to predict O_3 levels and inform emission control strategies. Thus an accurate representation of \mathcal{O}_3 production chemistry is vital for effective predictions, VOC degradation chemistry in MCM v3.1, CRI v2, MOZART-4, RADM2, RACM, RACM2, CBM-IV and CB05 were compared to that of the near-explicit MCM v3.2 mechanism. This chemistry was compared by tagging all organic degradation products over multi-day runs and calculating the Tagged Ozone Production Potential (TOPP) for each VOC. First day TOPP values were similar for most VOCs, larger discrepancies arose over the model run. O_x production was attributed to the number of carbon atoms in each degradation product showing that reduced mechanisms break down the emitted VOC quicker than more explicit mechanisms. Analysing the radical and PAN net production budgets illustrated that inclusion of production sources not included in the MCM v3.2 impacts $O_{\mathbf{x}}$ production.

1 Introduction

Ground-level ozone (O_3) is both an air pollutant and a short-lived climate forcing pollutant (SLCP) that is detrimental to human health and crop growth (EEA, 2013). O_3 is a

secondary pollutant as it is not directly emitted but produced from the reactions of volatile organic compounds (VOCs) and nitrogen oxides (NO_x = NO + NO₂) in the presence of sunlight (Atkinson, 2000).

Emissions of O_3 precursors have been steadily decreasing over Europe, however 98% of Europe's urban population are exposed to levels that exceed the World Health Organization (WHO) air quality guideline of $100 \ \mu g/m^3$ over an 8-hour mean (WHO, 2006). These exceedances are the result of local and regional emissions of O_3 precursor gases, their intercontinental transport and the non-linear relationship of O_3 concentrations on NO_x and VOC levels (EEA, 2013).

using chemical transport models (CTMs). This requires adequate representation of gas-phase chemistry in the chemical mechanism used by the CTM. Solving the concentrations of each chemical species is very computationally expensive and in regional and 3-D models simplified chemical mechanisms are used. Many chemical mechanisms are available, these were developed using differing streamlining approaches to gas-phase chemistry resulting in varying levels of simplification. This study compares the impacts

re-word

Effective emission reduction strategies require accurate predictions of O₃ concentrations

treatment of VOC degradation product chemistry by the chemical mechanism.

There is also a need to improve the accuracy of modelling studies from a scientific perspective. Abbatt et al. (2014) stresses the need to focus on the three fundamentals of

of these different simplified representations on O₃ production levels with a focus on the

atmospheric chemistry: observations, laboratory and modelling.

 ${
m O_3}$ is primarily produced and destroyed in the fast photochemical NO–NO $_2$ –O $_3$ cycle (R1)–(R3).

$$NO + O_3 \longrightarrow NO_2 + O_2$$
 (R1)

$$NO_2 + h\nu \longrightarrow NO + O(^3P)$$
 (R2)

$$O_2 + O(^3P) + M \longrightarrow O_3 + M$$
 (R3)

NO and NO₂ reach a near-steady state via (R1) and (R2) which is disturbed in two cases. Firstly, when O₃ is removed via (R1) which occurs during night-time or near large NO sources – NO_x-titration. Secondly, when O₃ is produced through VOC–NO_x chemistry (Sillman, 1999).

The odd oxygen family, O_x , is used to remove the influence of NO_x -titration on O_3

chemistry. In this study O_x is defined to include O_3 , NO_2 , $O(^3P)$, $O(^1D)$ and other chemical species that are involved in fast photochemical cycles with O_3 and NO_2 .

Emitted VOCs (RH) are typically oxidised in the atmosphere by reacting with the hydoxyl radical (OH) forming peroxy radicals (RO₂) in the presence of O₂ (R4). Further reactions of VOC degradation products produces RO₂ and hydroperoxy radicals (HO₂).

Both RO₂ and HO₂ radicals react with NO to produce NO₂ ((R5)-(R6)) leading directly to O₃ production via (R2) and (R3). Thus the amount of O₃ produced from the degradation of a VOC is directly related to the number of NO to NO₂ conversions by peroxy and hydroperoxy radicals (Atkinson, 2000).

$$RH + OH + O_2 \longrightarrow RO_2 + H_2O + O_2$$
 (R4)

$$RO_2 + NO \longrightarrow RO + NO_2$$
 (R5)

64

$$\mathrm{HO_2} + \mathrm{NO} \longrightarrow \mathrm{OH} + \mathrm{NO_2}$$
 (R6)

This chemistry leads to O₃ concentration being a non-linear function of the NO_x and VOCs concentrations. Three distinct atmospheric regimes with respect to O₃ production can be defined (Jenkin and Clemitshaw, 2000). In the NO_x-sensitive regime, VOC concentrations are much higher than those of NO_x and O₃ production is dependant on NO_x concentrations. On the other hand, when NO_x concentration is much higher than that of VOCs, it is the VOC concentration that determines the amount of O₃ produced. This is the VOC-sensitive regime. Finally, in the NO_x-VOC-sensitive regime there is maximal O₃ production which is controlled by both VOC and NO_x concentrations.

These different atmospheric regimes give rise to distinct radical removal mechanisms (Kleinman, 1991). In the NO_x-sensitive regime, the concentration of radicals is very high relative to NO_x causing radical removal by either radical combination reactions (R7) or bimolecular destruction reactions (R8) (Kleinman, 1994).

$$\mathrm{RO}_2 + \mathrm{HO}_2 \ \longrightarrow \ \mathrm{ROOH} + \mathrm{O}_2 \ (\mathrm{R7})$$

$${\rm HO_2 + OH} \quad \longrightarrow \ \, {\rm H_2O + O_2} \qquad ({\rm R8})$$

Whereas in the VOC-sensitive regime, high NO_x concentrations lead to radical removal by reaction with NO₂. These reactions lead to nitric acid (R9) and peroxy acetyl nitrate (PAN) species production (R10).

$$NO_2 + OH \longrightarrow HNO_3$$
 (R9)

$$RC(O)O_2 + NO_2 \longrightarrow RC(O)O_2NO_2$$
 (R10)

- In the NO_x-VOC-sensitive regime, the amount of radicals is comparable to the amount of NO_x leading to no dominant radical removal mechanism. Hence, radical and PAN chemistry play an important role in O₃ production as radical production helps fuel O₃ production and PAN acts as a reservoir species for both radicals and NO₂.
- VOCs impact O₃ production in different ways due to their diverse reaction rates and degradation pathways. Ozone Production Potentials (OPP) quantify the effect of individual VOCs on O₃ production. OPPs are typically been calculated through incremental reactivity (IR) studies. This involves changing the concentration of a particular VOC by a known increment and calculating the resulting change in O₃.
- Examples of IR scales are the Maximal Incremental Reactivity (MIR) and Maximum
 Ozone Incremental Reactivity (MOIR) scales in Carter (1994), as well as the Photochemical
 Ozone Creation Potential (POCP) scale of Derwent et al. (1996) and Derwent et al. (1998).
- Different NO_x conditions were used when calculating these IR scales thus calculating the OPPs of VOCs in different atmospheric regimes.
- IR calculations lack detailed mechanistic information about the processes affecting O₃ formation and combine both the direct and indirect effects of VOC degradation on O₃ production. The direct effect is the impact of the increased VOC concentration on O₃ production. This is related to the number of NO to NO₂ conversions from RO₂ produced during VOC degradation. Whereas the indirect effect is the influence of the increased radical species availability between the base VOC-mix and the increased VOC-mix on O₃ production.
- OPPs have been calculated using a tagging approach in Butler et al. (2011). All organic degradation products of a VOC are labelled with the name of the parent VOC enabling attribution of O_x production back to the emitted VOC. The Tagged Ozone Production Potential (TOPP) of a VOC is obtained by normalising the total daily O_x production by the total emissions of the VOC. The tagging approach follows each degradation pathway of each VOC making this approach ideal to compare the chemistry of different chemical mechanisms. Full details of the TOPP calculation is found in Section 2.
- Chemical mechanisms represent atmospheric chemistry in chemical transport models.

 All mechanisms have some level of simplification due to the computational resourses needed for gas-phase chemistry calculations. These levels of simplification arise from the different

scopes of modelling studies, for example a global CTM requires a more computational efficient mechanism than a boxmodel.

A near-explicit mechanism such as the Master Chemical Mechanism (MCM) (Jenkin et al., 2003; Saunders et al., 2003; Bloss et al., 2005) includes a large amount of mechanistic details (~ 12,000 reactions). This makes the MCM ideal as a reference mechanism when comparing chemical mechanisms. The latest version, MCM v3.2, (Rickard et al., 2014) is the reference mechanism in this study.

Further simplification is achieved by using either a lumped structure or a lumped molecule approach (Dodge, 2000). Lumped structure mechanisms speciate VOCs by the carbon bonds of the emitted VOC. Whilst in lumped molecule mechanisms, VOCs are represented by a specific organic or mechanism species representing a number of VOCs.

Different lumped molecule mechanisms use diverse approaches to creating mechanism species representing emitted VOCs.

Other chemical mechanism comparison studies consider O₃ concentration time series over varying VOC and NO_x concentrations. Examples of such studies are Dunker et al. (1984); Kuhn et al. (1998); Gross and Stockwell (2003) and Emmerson and Evans (2009). A common outcome is that the largest discrepancies in O₃ concentration times series arise when modelling urban rather than rural conditions. Other atmospheric species, such as PAN or H₂O₂, also show large concentration time series deviations between mechanisms.

IR scales have also been used as a tool for mechanism comparison. In Derwent et al. (2010), the near-explicit mechanisms MCM v3.1 and SAPRC-07 were compared using first-day POCP values calculated under VOC-sensitive conditions. In general, the POCP values were comparable between the mechanisms.

OPPs are a useful mechanism comparison tool as they relate O₃ production to a single number. In this study, TOPPs calculated for a number of VOCs using different mechanisms are compared to those calculated with the MCM v3.2. TOPPs are ideal for such a mechanism comparison study as they address multi-day scenarios and the tagging approach allows a detailed comparison of the VOC degradation chemistry between the mechanisms.

The chemical mechanisms compared and the methodology are described in Section 2. Section 3 presents the comparison of the first-day TOPPs and their time series.

Chemical	Number of	Number of	Type of
${f Mechanism}$	Organic Species	Organic Reactions	VOC Lumping
MCM v3.2	5708	16349	No lumping
MCM v3.1	4351	12691	No lumping
CRI v2	411	1145	No lumping*
MOZART-4	69	145	Lumped molecule
RADM2	44	103	Lumped molecule

RACM2	99	315	Lumped molecule
CBM-IV	20	45	Lumped structure
CB05	37	99	Lumped structure

Table 1: The chemical mechanisms used in the study, MCM v3.2 is the reference mechanism. References for the mechanisms are found within the main text. *The full CRI v2 is used and this has no lumping of the primary VOCs.

Detailed analysis of O_x production chemistry as well as the treatment of radical and PAN chemistry is compared in Section 4. Finally the conclusions and further work are in outlined Section 5.

2 Methodology

148 2.1 Chemical Mechanisms

The chemical mechanisms used in this study are outlined in Table 1. This includes the reference mechanism (MCM v3.2) and other mechanisms that are used for both global and regional modelling.

The Master Chemical Mechanism (MCM) (Jenkin et al., 1997, 2003; Saunders et al., 2003; Bloss et al., 2005; Rickard et al., 2014) is a near-explicit mechanism that describes the degradation of 125 primary VOCs. Whilst the large number of reactions makes the MCM computationally inefficient for use in regional or 3-D models, it is ideal as a reference in mechanism comparison studies. The latest version, MCM v3.2, is the reference mechanism in this study.

The second version of the Common Representative Intermediates (CRI v2) (Jenkin et al., 2008) is a reduced chemical mechanism which describes the oxidation of the same

primary VOCs as the MCM v3.1. VOC degradation is represented through degradation species whose O₃ production reflects that of the MCM v3.1. The full version of the CRI v2 (http://mcm.leeds.ac.uk/CRI) was used in this study.

Differences in O_3 production between the CRI v2 and MCM v3.2 may be due to differences between the MCM versions rather than the reduction techniques used in the CRI v2. For this reason, the MCM v3.1 is also included in this study.

The Model for OZone and Related chemical Tracers version 4 (MOZART-4) is a global chemical transport model including its own representation of tropospheric and stratospheric chemistry (Emmons et al., 2010). Methane, ethane, propane, ethene, propene, isoprene and α-pinene are represented by non-lumped model species. The mechanism species BIGALK,

BIGENE and TOLUENE represent all other VOC. The choice of mechanism species is based on the functional group of the VOC.

The second generation Regional Acid Deposition Model (RADM2) was developed for regional scale modelling of atmospheric chemistry (Stockwell et al., 1990). Methane, ethane, ethane, ethene and isoprene are represented by separate model species. All other VOCs are split into lumped model species based upon OH-reactivity and molecular weight.

RADM2 was updated to the Regional Atmospheric Chemistry Mechanism (RACM) (Stockwell et al., 1997). Updates include more mechanism species representing individual VOCs as well as revised rate constants and product yields. Aromatic, PAN and isoprene chemistry was also revised.

RACM2 is the most current version of the RACM mechanism (Goliff et al., 2013) with substantial updates to aromatic and ketone chemistry. More mechanism species representing emitted VOC are included in RACM2 leading to a more detailed mechanism than its previous versions.

The Carbon Bond Mechanism version four (CBM-IV) was developed for simulations of urban polluted conditions (Gery et al., 1989). Ethene, formaldehyde and isoprene are the only VOCs represented by specific species. All other emitted VOC are lumped according to their carbon bond types.

Initial concentrations of primary VOCs are split into the appropriate representation using the method described in Hogo and Gery (1989). For example, pentane has five single carbon bonds and is represented as 5 PAR. An initial concentration of 1,200 pptv would

be assigned as $6,000 (= 1,200 \times 5)$ pptv in CBM-IV.

The fifth version of the Carbon Bond Mechanism (CB05) (Yarwood et al., 2005) includes the mechanism species representing methane, ethane and acetaldehyde. The chemistry schemes were revised to include peroxide formation that occurs in VOC-sensitive regions. There were also updates in the allocation of some primary VOC to mechanism species.

2.2 Model Setup

The modelling approach and set-up followed that of the original TOPP study of Butler et al. (2011). A summary is provided, further details are found in the supplement to this paper and (Butler et al., 2011). Maximum O₃ production was achieved by emitting the amount of NO required to balance the source of radicals at each time step and was calculated following Kleinman (1991). The NO source was determined separately for each model run ensuring conditions of maximum O₃ production for each mechanism.

The NMVOC and their initial mixing ratios are those typical of Los Angeles and taken from Baker et al. (2008). The initial NMVOC mixing ratios were held constant until midday of the first day and then left to react freely. Methane (CH₄) was held fixed at 1.8 ppmv throughout. Carbon monoxide (CO) and O₃ were initialised at 200 ppbv and 40 ppbv respectively and then allowed to evolve freely.

Table 2 outlines the NMVOC used in the study, their initial mixing ratios and representation in the different mechanisms. Initial mixing ratios were weighted by carbon number of the mechanism species when lumping NMVOC into mechanism species. This ensured the amount of reactive carbon was constant between the model runs.

2.2.1 Mechanism Implementation

The MECCA boxmodel (Sander et al., 2011) is based upon the Kinetic Pre-Processor (KPP) (Damian et al., 2002). Hence, all chemical mechanisms were adapted into the modularised KPP format from their original format.

The MCM v3.2 inorganic chemistry reactions were used in each model run to focus on
the treatment of organic NMVOC degradation chemistry between mechanisms. Inorganic
gas-phase chemistry is well-known and any differences are typically due to inconsistencies

NMVOC	Mixing Ratio (ppbv)	Mixing Ratio MCM v3.1, v3.2 (ppbv) and CRI v2	MOZART-4	RADM2	RACM	RACM2	CBM-IV	CB05

Table 2: Typical NMVOCs present in Los Angeles and their respective mixing ratios (Baker et al., 2008) as well as their representation in each chemical mechanism. The representation of the VOCs in each mechanism is based upon the recommendations of the respective literature.

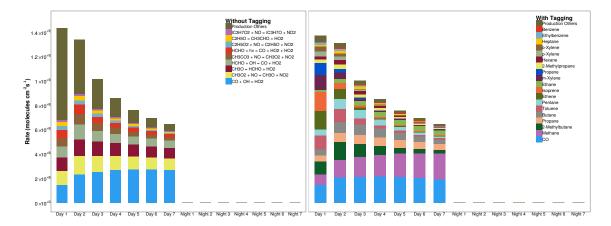

Figure 1: The O_x production budgets using the MCM v3.2 (a) without tagging and (b) with tagging, where O_x production is attributed to the emitted VOCs.

between IUPAC and JPL reaction rate constants (Emmerson and Evans, 2009).

Some mechanisms include reactions which are of importance only in the stratosphere or free troposphere. As this study is concerned with processes below the planetary boundary layer, these reactions were not included. For example, PAN photolysis was removed from MOZART-4, RACM2 and CB05 as it is only important in the free troposphere (Harwood et al., 2003).

The MCM v3.2 approach to photolysis, dry deposition and peroxy radical – peroxy radical reactions was used for each mechanism. The supplement to this article contains a detailed description of how this was implemented.

2.3 Tagged Ozone Production Potential (TOPP)

This section summarises the tagging methodology described in Butler et al. (2011) which should be consulted for more details.

232 2.3.1 Tagging Approach and Application to O_x Family

Tagging follows the degradation of all NMVOCs in Table 2 through all possible degradation
pathways. This is achieved by labelling every organic degradation product produced during
NMVOC degradation with the name of the emitted NMVOC. Thus, each NMVOC has its
own set of degradation reactions.

The tagging approach allows allocation of production and consumption budgets to

emitted NMVOCs. Without tagging, the individual reactions responsible for O_x production are determined but not the NMVOC source of the organic reactants. The NMVOC source

can be determined by exploiting the tags and this is illustrated in Figure 1.

2.3.2 Tagged Ozone Production Potential (TOPP) Definition

The daily Tagged Ozone Production Potential (TOPP) of a VOC is its total daily contribution to O_x production normalised by its total emissions on the first day of the model run. The O_x production of each VOC is determined by means of the tags as described in Section 2.3.1. The TOPP is a measure of the number of O_x molecules produced per molecule of emitted VOC.

3 Mechanism Comparison: Overall Results

248 3.1 First Day TOPP Value Comparison

The first day TOPP values calculated from each mechanism are compared to those calculated with the MCM v3.2 in Figure 2. The reduced mechanisms generally reproduce the MCM v3.2 first day TOPP values. However the TOPP values resulting from aromatic VOC degradation is underestimated in the reduced mechanisms.

Aromatic chemistry has always been difficult to represent in chemical mechanisms as
many products, their yields and reactions are not known or are subject to uncertainties
(Vereecken and Francisco, 2012). Thus, greater variation is expected between the TOPP
values of aromatic VOCs. The largest discrepancies are the zero TOPP values of toluene
and xylene in RACM. This is unrealistic as aromatic VOCs contribute significantly to O_x
production (Derwent et al., 1998). Section 3.2.1 outlines the chemistry responsible for
these results.

The first day TOPP values of 2-methylpropene in RACM, RACM2, CBM-IV and CB05 indicate that its degradation is treated very differently to the MCM v3.2. The variation between RACM, RACM2 and MCM v3.2 arise from the differences between the rate constants of the 2-methylpropene ozonolysis reactions. In MCM v3.2, this rate constant at 273 K is 1×10^{-17} cm³ s⁻¹ whereas in RACM and RACM2 it is about 25 times faster at 2.5×10^{-16} cm³ s⁻¹. This leads to more radical and hence O_x production

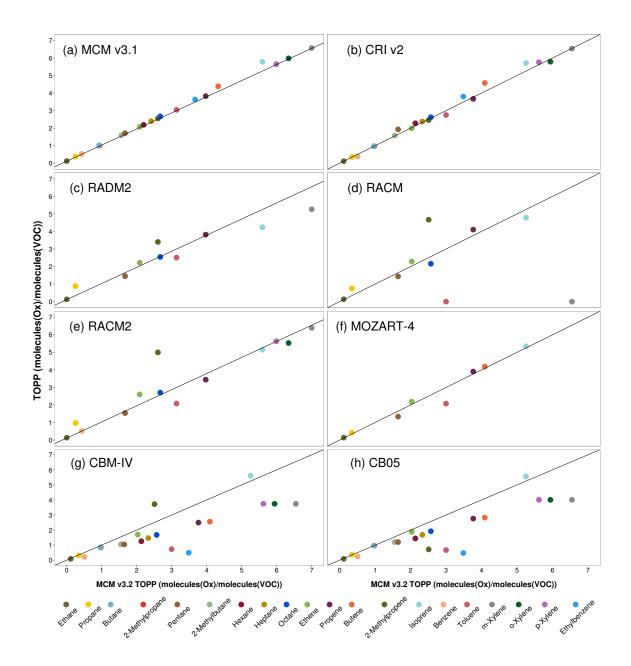

Figure 2: First day TOPP values obtained using (a) MCM v3.1, (b) CRI v2, (c) MOZART-4, (d) RADM2, (e) RACM, (f) RACM2, (g) CBM-IV and (h) CB05 mechanisms compared to the corresponding MCM v3.2 values.

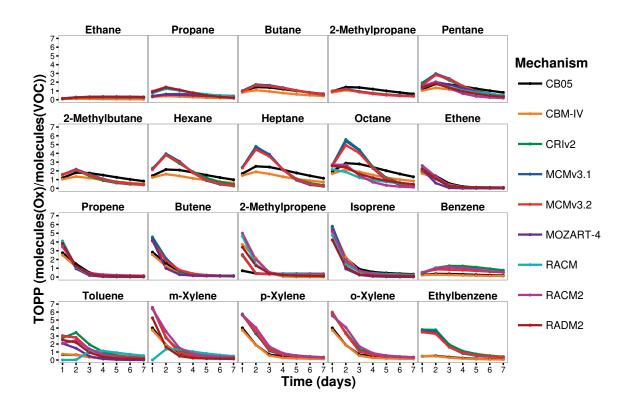

Figure 3: TOPP value time series for the NMVOC in Table 2 using the mechanisms of Table 1.

than in the MCM v3.2.

In CBM-IV, 2-methylpropene is represented by the mechanism species ALD2, which
is a surrogate for aldehydes with more than one carbon atom. ALD2 reacts very quickly
with OH forming CH₃CO₃, leading to O_x production. Furthermore, photolysis of ALD2
promotes radical and in turn O_x production. This is not a degradation pathway for
2-methylpropene in any other mechanism. The choice of 2-methylpropene representation
gives rise to more O_x production than in the MCM v3.2.

2-methylpropene representation was updated in CB05 to FORM + 3 PAR, where
FORM represents formaldehyde and PAR the paraffin C-C bond. The initial oxidation reactions of formaldehyde are similar to ALD2 whilst PAR is a slow reacting species. This slows down the O_x production resulting in lower O_x production than in the MCM v3.2.

3.2 TOPP Values Time Series

The time series of the daily TOPP values for all NMVOCs in Table 2 are presented in Figure 3. NMVOCs, such as ethene, whose degradation is described using dedicated

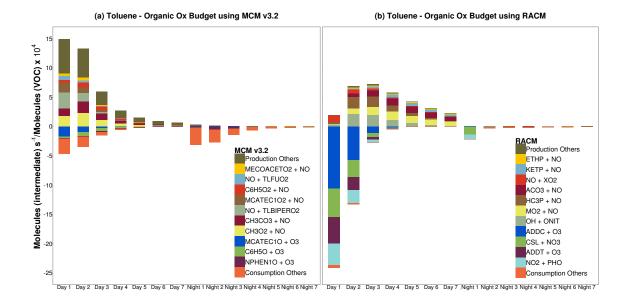

Figure 4: The O_x production and consumption budgets from toluene degradation in (a) MCM v3.2 and (b) RACM.

mechanism species have a narrow spread between their time series. Higher variability emerges between the time series of those NMVOCs, such as pentane, that are lumped mechanism species.

The second day maximum of all alkane TOPP time series is reproduced by all mechanisms except the RADM2, RACM and RACM2 representation of octane. O_x production is attributed to the carbon number of the NMVOC degradation products in Section 4.1 demonstrating that the reduced mechanisms break down the emitted NMVOC into species with a lower number of carbon atoms quicker than more detailed mechanisms.

In the case of octane, this break down proceeds so quickly that its TOPP value maximum is on the first day. The supplement to this paper contains details of the octane analysis.

The TOPP time series of aromatic NMVOCs show the highest variability between mechanisms. In particular, TOPP values of zero are obtained for both toluene and mechanisms. In particular, TOPP values of zero are obtained for both toluene and mechanisms. The rapid toluene break down in CBM-IV and CB05 results in a low TOPP time series. This impacts on the ethylbenzene TOPP value time series since it is represented as TOL + PAR.

3.2.1 RACM Aromatic Chemistry

The O_x production and consumption budgets due to toluene degradation in MCM v3.2 and RACM are depicted in Figure 4. The tagging approach allows attribution of these budgets to the responsible organic reactions.

RACM chemistry results in net O_x consumption on the first two days in contrast to the

MCM v3.2 which has net O_x production throughout. O_x consumption is mainly through

reaction of the cresol OH-adduct mechanism species ADDC with O₃. A fast rate constant

(5 × 10⁻¹¹ cm³ s⁻¹) was assigned to the this reaction making it the main reaction pathway

of ADDC. This reaction was included in RACM due to improved cresol product yields

when comparing RACM predictions with experimental data (Stockwell et al., 1997).

All other mechanisms that include cresol OH-adduct species do not include reaction with O_3 . The inclusion of aromatic OH-adduct species ozonolysis in RACM results in non-representative O_x production. This has been updated in RACM2 where aromatic OH-adduct species ozonolysis is no longer included.

4 NMVOC Degradation Analysis

$_{310}$ 4.1 Carbon Number of O_x Producing Degradation Products

The timing and amount of O_x produced throughout NMVOC degradation depends on how quickly the final degradation products of CO₂ and H₂O are reached (Butler et al., 2011). The day-time O_x production of pentane and toluene in all mechanisms is attributed to the number of carbon atoms of the degradation products in Figures 5 and 6 respectively. This allows comparison of how quickly the emitted NMVOC is broken down into smaller degradation products.

Figure 5 indicates that O_x production from degradation products having the same number of carbon atoms as the emitted NMVOC has a larger influence in the near-explicit mechanisms than reduced mechanisms. This is compensated by an increased amount of O_x production from degradation products having two or less carbon atoms. Thus the emitted VOC is broken down into smaller degradation products quicker in reduced mechanisms and cannot produce similar amounts of O_x to near-explicit mechanisms.

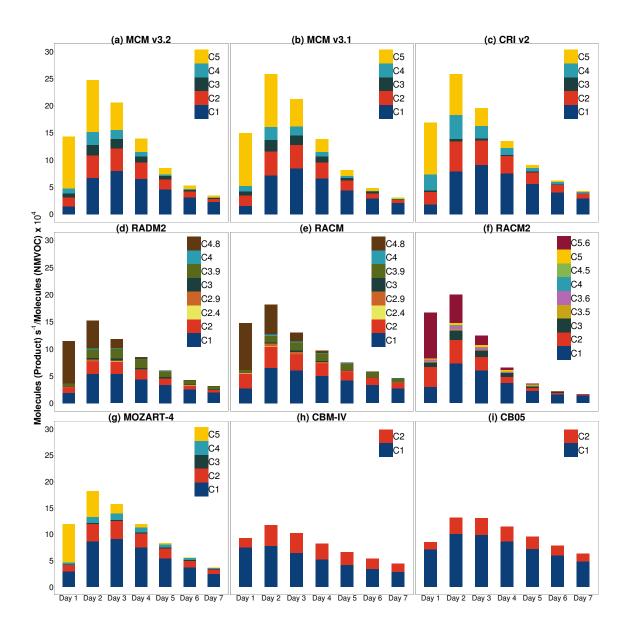

Figure 5: O_x production attributed to carbon number of degradation products during pentane degradation in (a) MCM v3.2, (b) MCM v3.1, (c) CRI v2, (d) RADM2, (e) RACM, (f) RACM2, (g) MOZART-4, (h) CBM-IV and (i) CB05.

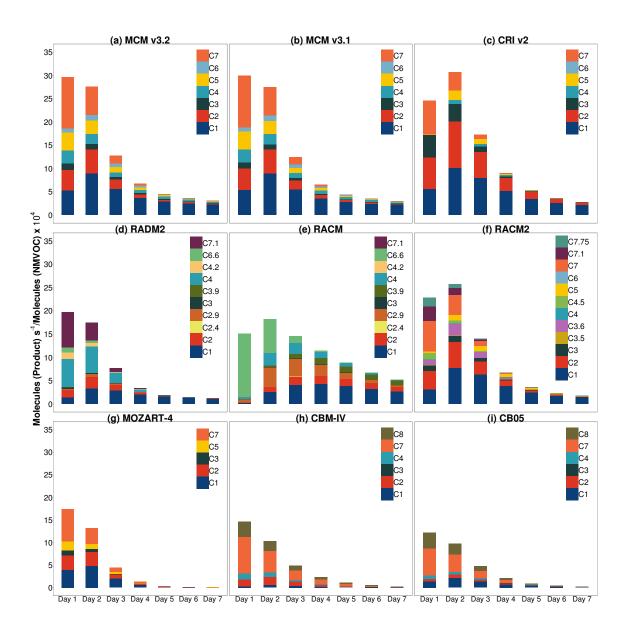

Figure 6: O_x production distributed by carbon number of degradation products during toluene degradation in (a) MCM v3.2, (b) MCM v3.1, (c) CRI v2, (d) MOZART-4, (e) RADM2, (f) RACM, (g) RACM2, (h) CBM-IV and (i) CB05. In RACM, net O_x consumption on the first two days is obtained as shown in Figure 4 and described in Section 3.2.1.

An extreme case is the toluene degradation in MOZART, CBM-IV and CB05 shown in Figure 6. Toluene is immediately broken down into degradation products having two or less carbon atoms. This results in much lower O_x production and TOPP values than other reduced mechanisms.

Toluene degradation in CRI v2 differs from all other mechanisms as it has maximum O_x

production on the second day. Larger O_x production from species having carbon number three or less than in the MCM v3.2 is responsible. This increase originates from extra HO₂

produced from the reaction of the carbonyl mechanism species CARB3 with OH. This is discussed further in the supplement to this paper. Jenkin et al. (2008) also acknowledge that reducing the MCM v3.1 chemistry of monoalkyl-substituted benzenes, such as toluene, was the most challenging and the resulting reduced chemistry over-estimates the O₃ mixing ratios.

RACM2 toluene degradation also reaches maximum O_x production on the second day. O_x production from degradation products of a similar or higher carbon number to toluene indicate that toluene is broken down at slower in RACM2 than in MCM v3.2.

338 4.2 Radical Production and Consumption Budgets

O_x production is directly to the conversion of NO to NO₂ by peroxy radicals. Moreover, in
this study maximum O₃ production was achieved by emitting the amount of NO required
to balance the radical source at each time step. A radical family for each mechanism
was used to investigate the processes affecting production and loss budgets. This radical
family includes all radical species and species involved in quick production and consumption
cycles, such as PAN species and HO₂NO₂.

The day-time net radical production and loss budgets due to alkane, alkene and aromatic degradation is shown in Figure 7. The largest differences arise from alkane and aromatic degradation. Pentane and toluene radical budgets are attributed to the responsible processes in Figures 8 and 9 to determine the source of these differences.

In general, photolysis is the major radical production process and the reactions of radicals with other species, such as NO and HO_2 , is the main radical sink. Reduced mechanisms include other processes to maintain radical production.

Figure 8 shows that initial VOC oxidation contributes to radical production in RADM2.

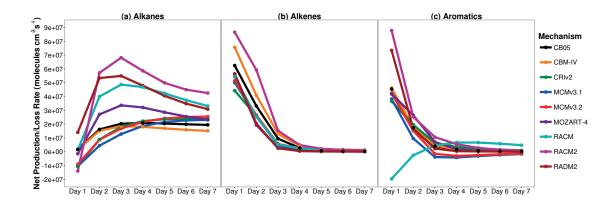

Figure 7: The day-time net budget contribution of (a) alkane, (b) alkene and (c) aromatic degradation on the radical family in each mechanism.

368

$$HC5 + OH \longrightarrow HC5P + 0.25 \text{ XO2} + H2O \text{ (R11)}$$

where HC5P is the pentyl peroxy radical and XO2 is an operator species which accounts

for extra NO to NO₂ conversions. XO2 is included in the radical family as it functions as a

peroxy radical. This additional radical production pathway is responsible for the net first

day radical production in RADM2.

The reactions of radicals lead to large net radical production in RACM after the first day. The main source being the reaction of HC5P with NO,

$${
m HC5P + NO} \longrightarrow 0.021 \; {
m HCHO} + 0.211 \; {
m ALD} + 0.722 \; {
m KET} \ + 0.599 \; {
m HO2} + 0.031 \; {
m MO2} + 0.245 \; {
m ETHP} \ + 0.334 \; {
m XO2} + 0.124 \; {
m ONIT} + 0.876 \; {
m NO2}$$

where HO2, MO2, ETHP and XO2 are the produced radical species. The larger net RADM2 and RACM radical production in Figure 7 is traced back to the extra radical production from reactions (R11) and (R12) respectively.

Radical production in CBM-IV and CB05 is largely impacted by NMVOC initial oxidation and production from other radical reactions. Pentane degradation in these mechanisms is very similar and the CB05 reactions are considered here.

Initial pentane degradation is via the PAR reaction with OH,

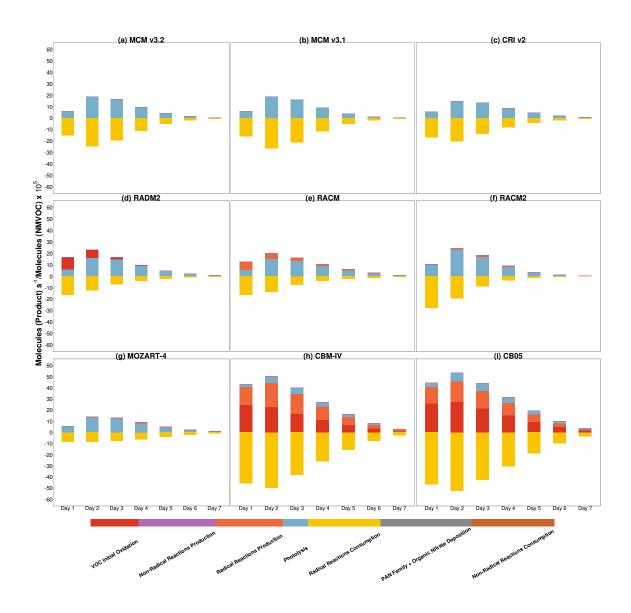

Figure 8: The processes influencing the radical family production and consumption budgets during pentane degradation are illustrated for (a) MCM v3.2, (b) MCM v3.1, (c) CRI v2, (d) RADM2, (e) RACM, (f) RACM2, (g) MOZART-4, (h) CBM-IV and (i) CB05.

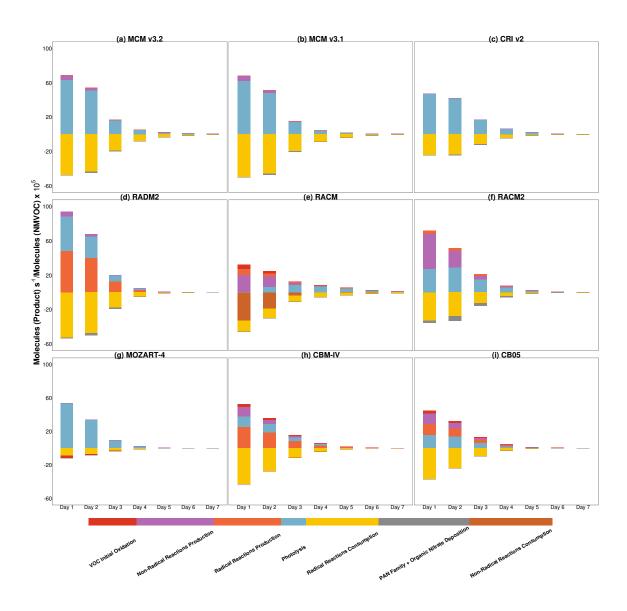

Figure 9: The processes influencing the radical family production and consumption budgets during toluene degradation is illustrated for (a) MCM v3.2, (b) MCM v3.1, (c) CRI v2, (d) RADM2, (e) RACM, (f) RACM2, (g) MOZART-4, (h) CBM-IV and (i) CB05.

XO2, HO2and ROR produced radical species. The 370 where are the mechanismspecies ROR decomposes immediately either HO20.96 XO2 + 0.04 XO2N + 0.94 HO2 + 0.6 ALD2 + 0.02 ROR + 0.5 ALDX - 2.1 PAR,once again XO2, HO2 and ROR are the produced radical species. The very fast decomposition of ROR and the use of XO2 to rapidly convert NO to NO2 leads to a rapid 374 loss of radicals. The large production and consumption processes are balanced so that the net radical production correlates with that of the MCM v3.2. 376

The first day net radical production due to aromatic degradation are overestimated using RADM2 and RACM2 chemistry and underestimated in RACM. The RACM underestimation results from the degradation chemistry discussed in Section 3.2.1.

Figure 9 indicates that the RACM2 overestimation is due to radical production from reactions that do not involve radicals. The ozonolysis of the unsaturated dicarbonyl mechanism species DCB1 and DCB2 as well as the epoxy mechanism species EPX are additional reactions used to produce radicals.

The MCM v3.2 species TLEPOXMUC is analogous to EPX in RACM2. The ozonolysis rate constants are 5×10^{-18} and 1×10^{-16} cm³ s⁻¹ respectively. The RACM2 rate constant is 20 times larger than that of the MCM v3.2 leading to excess radical production in RACM.

The ozonolysis of dicarbonyl species are included in RACM2 based on the recommendations of Bierbach et al. (1994). Dicarbonyl ozonolysis was not included in the MCM due to the uncertainties of these reactions (Bloss et al., 2005). This additional radical source leads to larger net radical production.

992 4.3 PAN Production and Consumption Budgets

PAN chemistry influences O_x production as it is both a radical and NO_x sink (Fischer et al., 2014). PAN production and consumption budgets were compared using a PAN family for each mechanism. This PAN family included all PAN species and associated acyl peroxy radicals.

Figure 10 shows the net day-time budgets of the PAN family from alkane, alkene and aromatic degradation. The PAN production and consumption budgets due to pentane and toluene degradation are expressed in terms of the contributing processes in Figures 11

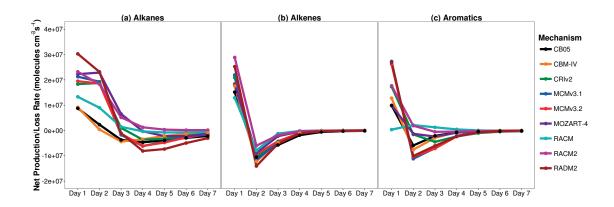

Figure 10: The day-time net budget contribution of (a) alkane, (b) alkene and (c) aromatic degradation on the PAN family in each mechanism.

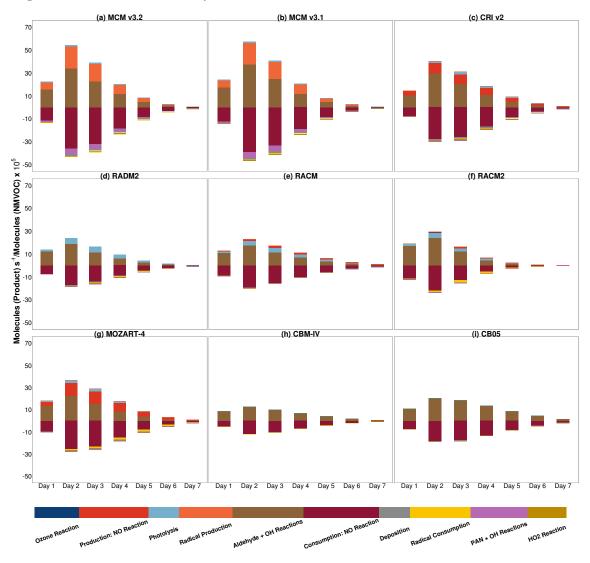

Figure 11: The processes influencing the PAN family production and loss budgets during pentane degradation are illustrated for (a) MCM v3.2, (b) MCM v3.1, (c) CRI v2, (d) RADM2, (e) RACM, (f) RACM2, (g) MOZART-4, (h) CBM-IV and (i) CB05.

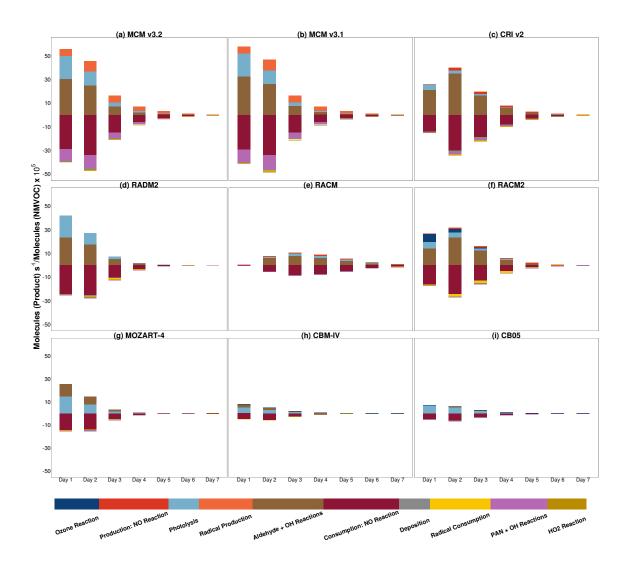

Figure 12: The processes contributing to PAN family production and loss during toluene degradation are shown for (a) MCM v3.2, (b) MCM v3.1, (c) CRI v2, (d) RADM2, (e) RACM, (f) RACM2, (g) MOZART-4, (h) CBM-IV and (i) CB05.

and 12 respectively. Similar to the net radical budget analysis in Section 4.2, the largest differences are from alkane and aromatics degradation.

Overall, reactions of aldehydes with OH are the main PAN family source with (R14) being the most prominent. The reaction of NO with acyl peroxy radicals is the major sink where (R15) is the main contributor. Other processes also impact production and consumption and these differ between mechanisms.

$$\mathrm{CH_{3}CHO} + \mathrm{OH} \longrightarrow \mathrm{CH_{3}CO_{3}} + \mathrm{H_{2}O} \quad (\mathrm{R}14)$$

406

422

$$\mathrm{CH_3CO_3} + \mathrm{NO} \longrightarrow \mathrm{CH_3O_2} + \mathrm{NO_2}$$
 (R15)

PAN family production in both MCM mechanisms is further fuelled by alkoxy radical decomposition. This process is not included in any reduced mechanism and additional PAN family production is obtained through photolysis and reactions involving NO or O₃.

CBM-IV and CB05 do not include any additional PAN family sources in alkane degradation. Whilst during aromatic degradation the additional PAN family source due to photolysis is minor. This results in lower net PAN family production compared to other mechanisms.

RADM2 has large net PAN family production regardless of the NMVOC type. The (R15) rate constant is ~ 60% slower than that of the MCM v3.2 rate constant resulting in less PAN family consumption. This rate constant was updated in RACM whilst the rate constant of (R14) was not significantly changed. This leads to more PAN family consumption in RACM and lower net PAN family production.

The detailed aromatic degradation chemistry of the MCM mechanisms produces the largest net PAN family production. The main sources of PAN family in the MCM are methyl glyoxal photolysis (R16) and reaction with OH (R17).

$$MGLYOX + h\nu \longrightarrow CH_3CO_3 + CO + HO_2$$
 (R16)
 $MGLYOX + OH \xrightarrow{O_2} CH_3CO_3 + CO + H_2O$ (R17)

In RADM2 and MOZART-4, (R16) and (R17) are also the main PAN family production sources. This contrasts to CRI v2 and RACM2 where these reactions are not as significant as PAN family production from (R14) and (R18).

$$C_2H_5CHO + OH \longrightarrow C_2H_5CO_3 + H_2O$$
 (R18)

The PAN family production budgets in CRI v2 and RACM2 in Figure 12 peak on the second day rather than the first, similar to their O_x production budgets in Figure 6. As outlined in Section 4.1, CRI v2 toluene degradation has a larger contribution from degradation products with a carbon number three or less. This is reflected in CRI v2 PAN family production where the largest contributions are from reactions of CH₃CHO and C₂H₅CHO.

The RACM2 ozonolysis reactions of unsaturated dicarbonyls are an additional PAN family source not included in other mechanisms. These reactions have a double contribution to PAN family production. Firstly, the mechanism acyl peroxy radical species RO3 is produced which sets off a reaction chain with CH₃CHO, represented as ALD in RACM2, being produced. These additional reactions result in a very different PAN family budget when compared to MCM v3.2.

5 Conclusions

Tagged Ozone Production Potentials (TOPPs) were used to compare the NMVOC degradation in reduced chemical mechanisms to the near-explicit MCM v3.2. The first day NMVOC TOPP values in all mechanisms are generally comparable to those of the MCM v3.2. TOPP value time series over multi-day scenarios have larger differences. Thus differences in O_x production between reduced mechanisms and near-explicit mechanisms has a larger impact over multi-day scenarios.

The largest discrepancies from the MCM v3.2 are the zero TOPP values of toluene and m-xylene in RACM. These are due to the net O_x consumption from ozonolysis of aromatic-OH adduct species.

Attributing O_x production budgets to the number of carbon atoms of each degradation species showed that reduced mechanisms break down NMVOCs faster than near-explicit mechanisms. This leads to reduced mechanisms being unable to reach the O_x levels of near-explicit mechanisms.

Radical and PAN family production and consumption budgets were analysed in detail
through tagging. Photolysis is the main radical souce in the MCM v3.2 whilst reduced
mechanisms also produce radicals by thermal reactions. This leads to larger net radical

production than in MCM v3.2.

Alkoxy radical decomposition is a PAN family production source in the MCM v3.2 that is substituted by thermal reactions or photolysis in reduced mechanisms. This leads to different PAN family chemistry in reduced mechanisms which impacts both radical and O_x production.

The tagging approach and TOPP calculation over multi-day scenarios have proven to be a useful tool in comparing the chemical degradation pathways in chemical mechanisms. This approach could be used to further investigate how mechanisms treat degradation chemistry under more realistic NO_x conditions or a range of NO_x conditions, simulating different atmospheric regimes.
